

5.1 Contour-based techniques for image segmentation

Image segmentation is the process of **assigning a label to every pixel in an image** such that pixels with the same label share certain characteristics. As a consequence, it produces regions whose pixels have similar properties (e.g. intensity, color, texture, or location in the image) which have a geometric and semantic meaning (see Fig.1). The result of image segmentation could be:

- a set of segments that collectively cover the entire image (e.g. thresholding),
- or a set of contours extracted from the image (e.g. edge detection).

No description has been provided for this image

Fig. 1: Example of image segmentation where each region corresponds to an object in the scene.

Conceptually, two traditional approaches to image segmentation exist (see Fig. 2):

- **Top-down segmentation** (*semantic segmentation*), which considers that pixels from the same object in the scene should be in the same segmented region.
- **Bottom-up segmentation** (*pixel-driven segmentation*), which establishes that similar pixels in the image must be in the same segmented region.

No description has been provided for this image

Fig. 2. An example of top-down and bottom-up approaches. Adopted from [1]

We put the spotlight here on bottom-up segmentation approaches. Methods following such approach can be grouped into:

- **Contour-based techniques**, which attempt to identify the image regions by detecting their contours.
- **Region-based techniques** that group together pixels that are similar.

In this book we are going to experience both, starting with **contour-based techniques**, whose are based on detecting specific contours in the image (e.g. circles). In this context, image contours are defined as edge pixels that enclose a region.

Contour-based techniques could be roughly classified into:

- **Local techniques.** Try to segment regions by detecting closed contours, which typically enclose pixels with similar intensities.
 - LoG + zero crossing.
 - Edge following (Canny operator).
- **Global techniques.** Detect particular shapes in the image (circles, lines, etc.).
 - Hough transform.

This notebook will cover the **Hough transform** (section 5.1.1), a contour-based technique that can be used for detecting regions with an arbitrary shape in images.

Problem context - Self-driving car

A prestigious company located at PTA (The Andalusia Technology Park) is organizing a [hackathon](#) for this year in order to motivate college students to make further progress in the autonomous cars field. Computer vision students at UMA decided to take part in it, but the organizers have posed an initial basic task to guarantee that participants have expertise in image processing techniques.

This way, the company sent to students a task for **implementing a basic detector of road lane lines using OpenCV in python**. We are lucky! These are two tools that we know well ;).

Detecting lines in a lane is a fundamental task for autonomous vehicles while driving on the road. It is the building block to other path planning and control actions like breaking and steering.

So here we are! We are going to detect road lane lines using Hough transform in OpenCV.

```
In [1]: import numpy as np
import cv2
import math
import matplotlib.pyplot as plt
import matplotlib
import scipy.stats as stats

matplotlib.rcParams['figure.figsize'] = (10.0, 10.0)
images_path = './images/'
```

5.1.1 Hough transform

The **Hough Transform** is a technique for the detection of arbitrary shapes in an image. For that, such shapes must be expressed in:

- analytical form (**classic Hough**), e.g. using the mathematical representation of lines, circles, ellipses, etc, or
- in a numerical form (**generalized Hough**) where the shape is given by a table.

Since our goal is to detect lines, we will focus here on analytically expressed shapes. Specifically, a line can be represented analytically as:

$$y = mx + n$$

or in its parametric form, as:

$$\rho = x \cos \theta + y \sin \theta$$

where ρ is the perpendicular distance from the origin $(0, 0)$ to the line, and θ is the angle formed by this perpendicular line and the horizontal axis measured in counter-clockwise (see Fig. 3). Thereby, we are going to represent lines using the pair of parameters (ρ, θ) .

Fig. 3. Parametric representation of a line.

The Hough transform works by a voting procedure, which is carried out in a parameter space (ρ, θ in our case). This technique consists of the following steps:

- 1. Build an accumulator matrix**, where rows index the possible values of ρ , and columns those for θ . For example, if the possible values for ρ are $0, 1, 2, \dots, d$ (where d is the max distance e.g. diagonal size of the image) and those for θ are $0, 1, 2, \dots, 179$, the matrix shape would be $(d, 180)$.

```
In [2]: # Define possible rho and theta values
theta_values = [0,np.pi/4,np.pi/2,3*np.pi/4]
rho_values = [0,1,2,3,4,5]

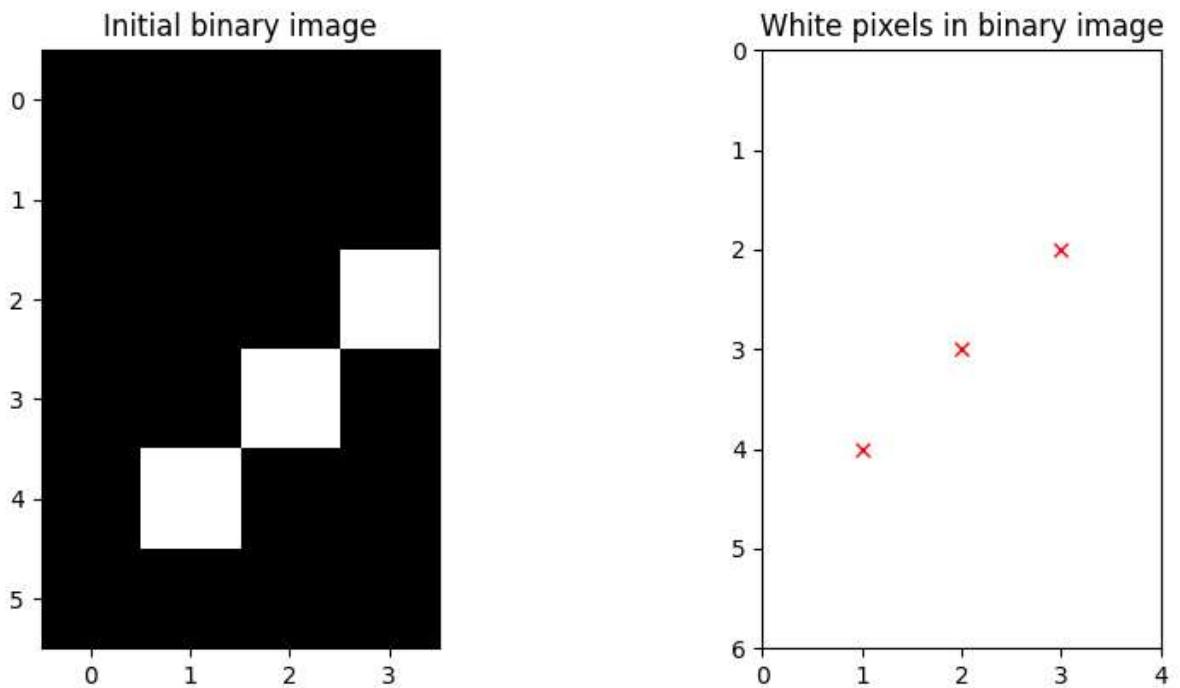

# Create the accumulator
acc = np.zeros([len(rho_values),len(theta_values)])
```

- 2. Binarize the input image** to obtain pixels that are candidates to belong to the shape contours (e.g. by applying an edge detector).

```
In [3]: # Coordinates of white points in binary image
xs = np.array([1,2,3])
ys = np.array([4,3,2])

# Initial image
plt.subplot(221)
blank_image = np.zeros((6,4,1), np.uint8)
blank_image[ys,xs] = 255
plt.imshow(blank_image, cmap='gray');
plt.title('Initial binary image')

# Show them!
plt.subplot(222)
plt.plot(xs,ys, 'rx')
plt.axis('scaled')
axes = plt.gca()
axes.set_xlim([0,4])
axes.set_ylim([0,6])
plt.gca().invert_yaxis()
plt.title('White pixels in binary image');
```

3. For each candidate (white pixel):

- A. **Evaluate:** Since the point coordinates (x, y) are known, place them in the line parametric form and iterate over the possible values of θ to obtain the values for ρ . In the previous example $\rho_i = x \cos \theta_i + y \sin \theta_i, \forall i \in [0, 180]$
- B. **Vote:** For every obtained pair (ρ_i, θ_i) increment by one the value of its associated cell in the accumulator.

If we do this with an accumulator with an enough resolution, we would get a sinusoid.

```
In [4]: # For each white pixel

for i in range (0,len(xs)):
    x = xs[i]
    y = ys[i]

    # Show the point voting
    subplot_index = str(32) + str(i*2+1)
    plt.subplot(int(subplot_index))
    plt.axis('scaled')
    axes = plt.gca()
    axes.set_xlim([0,4])
    axes.set_ylim([0,6])

    plt.plot(xs,ys,'rx')
    plt.plot(x,y,'co')

    plt.title('Pixel being evaluated at iteration ' + str(i+1))
    plt.gca().invert_yaxis()

    # Evaluate the (x,y) coordinates for different values of theta, and
    # retrieve rho
    for theta_index in range(0,len(theta_values)):
        theta = theta_values[theta_index]
        rho = x*np.cos(theta) + y*np.sin(theta)
        rho = int(np.round(rho))
        # Vote!
        acc[rho][theta_index] += 1.0
```

```

# Show the accumulator
subplot_index = str(32) + str(i*2+2)
plt.subplot(int(subplot_index))
plt.imshow(acc,cmap='gray',vmax=3);
plt.xticks([0, 1, 2, 3], ['0','pi/4','pi/2','3pi/4'])

plt.title('Accumulator values')

```

4. Finally, **obtain the shape candidates** by setting a threshold to control how many votes needs a pair (ρ, θ) to be considered a line, and by applying local maxima in the accumulator space.

Fig. 3. Left, image space. Right, parameter space illustrating the evolution of the votes. Note that in this example θ have only 8 possible values.

The idea behind this algorithm is that when a pixel in the image space votes for all the lines that go through it in the parameter space, when a second pixel belonging to the same line votes, then the line connecting both pixels would have two votes.

OpenCV pill

OpenCV implements the method `cv2.HoughLines()` for detecting lines using the Hough transform. However, prior to its usage, and as commented in the `step 1.` of the algorithm, it is needed a binary image. For that we are going to resort to our old friend the Canny algorithm, so the detected edges will be the white pixels in the binary image.

As we now, noisy images seriously hamper the performance of computer vision techniques, and since `cv2.Canny()` does not include blurring, we provide here a method called `gaussian_smoothing()` to assist you in that task.

```
In [5]: def gaussian_smoothing(image, sigma, w_kernel):
    """ Blur and normalize input image.

    Args:
        image: Input image to be binarized
        sigma: Standard deviation of the Gaussian distribution
        w_kernel: Kernel aperture size

    Returns:
        binarized: Blurred image
    """

    # Define 1D kernel
    s=sigma
    w=w_kernel
    kernel_1D = [np.exp(-z*z/(2*s*s))/np.sqrt(2*np.pi*s*s) for z in range(-w,w+1)]

    # Apply distributive property of convolution
    kernel_2D = np.outer(kernel_1D,kernel_1D)

    # Blur image
    smoothed_img = cv2.filter2D(image,cv2.CV_8U,kernel_2D)

    # Normalize to [0 254] values
    smoothed_norm = np.array(image.shape)
    smoothed_norm = cv2.normalize(smoothed_img,None, 0, 255, cv2.NORM_MINMAX)

    return smoothed_norm
```

ASSIGNMENT 1: Detecting lines with Hough

Your first task is to apply `cv2.HoughLines()` to the image `car.png`, a test image taken from the frontal camera of a car. Draw the resultant lines using `cv2.line()`.

The main inputs of `cv2.HoughLines()` are:

- *image*: binary input image

- *rho*: distance resolution of the accumulator in pixels (usually 1, it may be bigger for high resolution images)
- *theta*: angle resolution of the accumulator in radians. (usually $\frac{\pi}{180}$)
- *threshold*: only line candidates having a number of votes $>$ threshold are returned.

And it returns:

- a ($n_lines \times 1 \times 2$) array containing, in each row, the parameters of each detected line in the $[\rho, \theta]$ format.

Note that, for drawing the lines, you have to transform the resultant lines from the (ρ, θ) space to Cartesian coordinates.

Try different parameter values until you get something like this:

Fig. 4. Example of lines detection.

```
In [6]: # Assignment 1
# Read the image
image = cv2.imread(images_path + "car.png", -1)

# Convert to RGB and get gray image
image = cv2.cvtColor(image, cv2.COLOR_BGR2RGB)
gray = cv2.cvtColor(image, cv2.COLOR_RGB2GRAY)

# Blur the gray image
gray = gaussian_smoothing(gray, 2, 5)

# Apply Canny algorithm
edges = cv2.Canny(gray, 100, 200, apertureSize = 3)

# Search for Lines using Hough transform
lines = cv2.HoughLines(edges, rho=1, theta=(np.pi/180), threshold=163)

# For each line
for i in range(0, len(lines)):

    # Transform from polar coordinates to cartesian coordinates
    rho = lines[i][0][0]
    theta = lines[i][0][1]

    a = math.cos(theta)
    b = math.sin(theta)

    x0 = a * rho
    y0 = b * rho

    # Get two points in that line
    x1 = int(x0 + 2000*(-b));
    y1 = int(y0 + 2000*(a))
    pt1 = (x1,y1)
    x2 = int(x0 - 2000*(-b))
    y2 = int(y0 - 2000*(a))
    pt2 = (x2,y2)

    # Draw the Line in the RGB image
    cv2.line(image, pt1, pt2, (255,0,0), 3, cv2.LINE_AA)
```

```
# Show resultant image
plt.imshow(image);
```

5.1.2.1 Probabilistic Hough transform

For high-resolution images and large accumulator sizes the Hough transform may need long execution times. However, in applications like autonomous cars a fast execution is mandatory. For example, having a car moving at 100km/h covers ~ 28 meters in a second. Imagine how much lines can change in that time!

OpenCV pill

OpenCV provides with the method `cv2.HoughLinesP()` a more complex implementation of the Hough Line Transform, which is called **probabilistic Hough Transform**. This alternative does not take all the points in the binary image into account, but a random subset of them that are still enough for line detection. This also results in lower thresholds when deciding if a line exists or not.

ASSIGNMENT 2: Another option for detecting lines

Apply `cv2.HoughLinesP()` to the image `car.png` and draw the detected lines.

This function returns:

- line segments `[x1,y1,x2,y2]` instead of the line equation parameters.

For that, two additional arguments are needed:

- `minLineLength`: line segments shorter than that are rejected.
- `maxLineGap`: maximum allowed gap between points on the same line to link them.

Try different parameter values until you get something like this:

Fig. 5. Lines detection example with the probabilistic Hough Transform.

```
In [7]: # Assignment 2
# Read the image
image = cv2.imread(images_path + "car.png",-1)

# Convert to RGB and get gray image
image = cv2.cvtColor(image, cv2.COLOR_BGR2RGB)
gray = cv2.cvtColor(image, cv2.COLOR_RGB2GRAY)

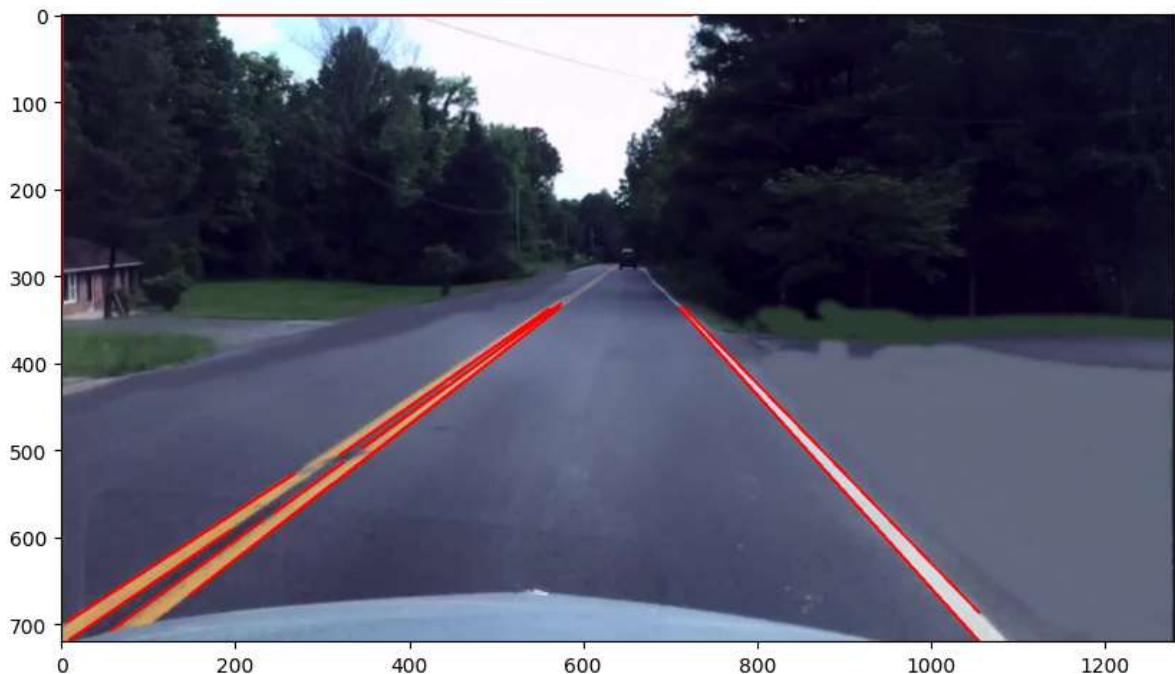

# Blur the gray image
gray = gaussian_smoothing(gray,1,2)

# Apply Canny algorithm
edges = cv2.Canny(gray,100,200,apertureSize = 3)

# Search for Lines using probabilistic Hough transform
rho = 1
theta = np.pi/180
threshold = 155
lines = cv2.HoughLinesP(edges, rho, theta, threshold,
                        minLineLength=50,maxLineGap=8)
# For each line
for line in lines:

    # Draw the Line in the RGB image
    x1,y1,x2,y2 = line[0]
    cv2.line(image,(x1,y1),(x2,y2),(255,0,0),2)

# Show resultant image
plt.imshow(image);
```

Thinking about it (1)

Now that you have played with the Hough Transform, **answer the following questions:**

- In the first assignment, we obtained an image with a number of red lines drawn on it. However, these lines goes over pixels in the image that do not contains lines! (e.g. belonging to the sky). What could we do to fix this, that is, obtain the pixels belonging to lines in the image?

Esto se debe a que la función cv2.HoughLines nos devuelve un vector de pares $(\theta, r\theta)$, donde estas $r\theta$ no están delimitadas, por tanto las líneas son trazadas hasta el final de la imagen.

Para arreglar esto, deberíamos hacer uso de cv2.HoughLinesP, que nos devuelve los extremos de las líneas detectadas, haciendo que sea posible delimitarlas.

- Without restrictions regarding execution time, which method would you use, Hough Transform or its probabilistic counterpart?

Teniendo en cuenta lo anterior, su contraparte probabilística es una mejor opción, ya que da un resultado mucho más preciso ya a cambio de un tiempo de ejecución más largo.

- Could there be a cell in the accumulator with a value higher than the number of white pixels in the binary image? why?

No es posible, ya que cada pixel blanco de la imagen de los bordes puede votar a cada celda de la matriz una única vez, debido a que se vota a un par (ρ_i, θ_i) donde el valor de θ_i no se puede repetir más de una vez por iteración, y dado que el número de iteraciones corresponde al número de píxeles blancos, entonces el valor máximo de una celda del acumulador no puede ser mayor que el número de píxeles blancos.

- Which should be the maximum value for ρ in the accumulator? Why?

Depende de la resolución de la imagen, por lo general un valor de 1 es suficiente, sin embargo podemos necesitar un valor mayor para imágenes de mayor resolución.

OPTIONAL

Think about any other application where the finding of straight lines could be useful. Get some images related to said application and detect lines with the Hough transform!

END OF OPTIONAL PART

Conclusion

Terrific work! In the road lane lines detection context you have learned:

- to detect shapes in images using Hough transform .

Also, you obtained some knowledge about:

- self-driving cars and computer vision, and
- lane line detection for autonomous cars.

See you in the next one! Keep learning!

5.2 Region-based techniques for image segmentation

In the previous notebook we had fun with contour based techniques for image segmentation. In this one we will play with region-based techniques, where the resulting segments cover the entire image. Concretely we will address two popular region-based methods:

- K-means ([section 5.2.1](#))
- Expectation-Maximization (EM, [section 5.2.2](#))

Problem context - Color quantization

Color quantization is the process of reducing the number of distinct colors in an image while preserving its color appearance as much as possible. It has many applications, like image compression (e.g. GIFs, which only support 256 colors!) or [content-based image retrieval](#).

Image segmentation techniques can be used to achieve color quantization, let's see how it works!

```
In [1]: import numpy as np
import cv2
import matplotlib.pyplot as plt
import matplotlib
import scipy.stats as stats
from ipywidgets import interact, fixed, widgets
matplotlib.rcParams['figure.figsize'] = (10.0, 10.0)
images_path = './images/'

import sys
sys.path.append("..")
from utils.PlotEllipse import PlotEllipse
```

5.2.1 K-Means

As commented, region-based techniques try to group together pixels that are similar. Such issue is often called the *clustering problem*. Different attributes can be used to decide if two pixels are similar or not: intensity, texture, color, pixel location, etc.

The **k-means algorithm** is a region-based technique that, given a set of elements (image pixels in our case), makes K clusters out of them. Thereby, it is a perfect technique for addressing color quantization, since our goal is to reduce the color palette of an image to a fixed number of colors K . Concretely, k-means aims to minimize the sum of squared Euclidean distances between points x_i in a given space (e.g. grayscale or RGB color representations) and their nearest cluster centers m_k :

$$\arg \min_M D(X, M) = \sum_{\text{Cluster } k} \sum_{\text{point } i \text{ in cluster } k} (x_i - m_k)^2$$

In our case, the point x_i could be interpreted as a **feature vector** describing the i^{th} pixel that, as mentioned, could include information like the pixel color, intensity, texture, etc. Thus, m_k represents **the mean of the feature vector** of the pixels in cluster k .

Let's see how the k-means algorithm works in a color domain, where each pixel is represented in a feature n-dimensional space (e.g. grayscale images define a 1D feature space, while RGB images a 3D space):

1. Pick the number K , that is, the number of clusters in which the image will be segmented (e.g. number of colors).
2. Place K centroids m_k in the color space (e.g. randomly), these are the centers of the regions.
3. Each pixel is assigned to the cluster with the closest centroid, hence creating new clusters.

Fig 1. Example in a 2D space (e.g. YCbCr color space) with 3 clusters. Each point is assigned to its closest centroid

4. Compute the new means m_k of the K clusters.

Fig 2. Example of how the centroids evolve over time

5. Repeat steps 3 and 4 until convergence, that is, some previously defined criteria is fulfilled (e.g. the centers of regions do not move, or a certain number of iterations is reached).

Fig 3. Final segmentation result

This procedure is the same independently of the number of dimensions in the workspace.

This technique presents a number of pros and cons:

- **Pros:**
 - It's simple.
 - Convergence to a local minima is guaranteed (but no guarantee to reach the global minima).
- **Cons:**
 - High usage of memory.
 - The K must be fixed.
 - Sensible to the selection of the initialization (initial position of centroids).
 - Sensible to outliers.
 - Circular clusters in the feature space are assumed (because of the usage of the Euclidean distance)

K-means toy example

Luckily for us, OpenCV defines a method that perform k-means: `cv2.kmeans()`, [here you can find a nice explanation](#) about how to use it. Let's take a look at a toy 1D k-means example in

order to get familiar with it. The following function, `binarize_kmeans()`, binarizes an input `image` by executing the K-means algorithm, where the `it` sets its maximum number of iterations.

Note that the stopping criteria can be either:

- if a maximum number of iterations is reached, or
- if the centroid moved less than a certain `epsilon` value in an iteration.

```
In [2]: def binarize_kmeans(image,it):
    """ Binarize an image using k-means.

    Args:
        image: Input image
        it: K-means iteration
    """

    # Set random seed for centroids
    cv2.setRNGSeed(124)

    # Flatten image
    flattened_img = image.reshape((-1,1))
    flattened_img = np.float32(flattened_img)

    #Set epsilon
    epsilon = 0.2

    # Establish stopping criteria (either `it` iterations or moving Less than `epsilon`)
    criteria = (cv2.TERM_CRITERIA_EPS + cv2.TERM_CRITERIA_MAX_ITER, it, epsilon)

    # Set K parameter (2 for thresholding)
    K = 2

    # Call kmeans using random initial position for centroids
    _,label,center=cv2.kmeans(flattened_img,K,None,criteria,it, cv2.KMEANS_RANDOM_CENTRE)

    # Colour resultant labels
    center = np.uint8(center) # Get center coordinates as unsigned integers
    print(center)
    flattened_img = center[label.flatten()] # Get the color (center) assigned to each

    # Reshape vector image to original shape
    binarized = flattened_img.reshape((image.shape))

    # Show resultant image
    plt.subplot(2,1,1)
    plt.title("Original image")
    plt.imshow(binarized, cmap='gray', vmin=0, vmax=255)

    # Show how original histogram have been segmented
    plt.subplot(2,1,2)
    plt.title("Segmented histogram")
    plt.hist([image[binarized==center[0]].ravel(), image[binarized==center[1]].ravel()])
```

As you can see, `cv2.kmeans()` returns two relevant arguments:

- `label`: Integer array that stores the cluster index for every pixel.
- `center`: Matrix containing the cluster centroids (each row represents a different centroid).

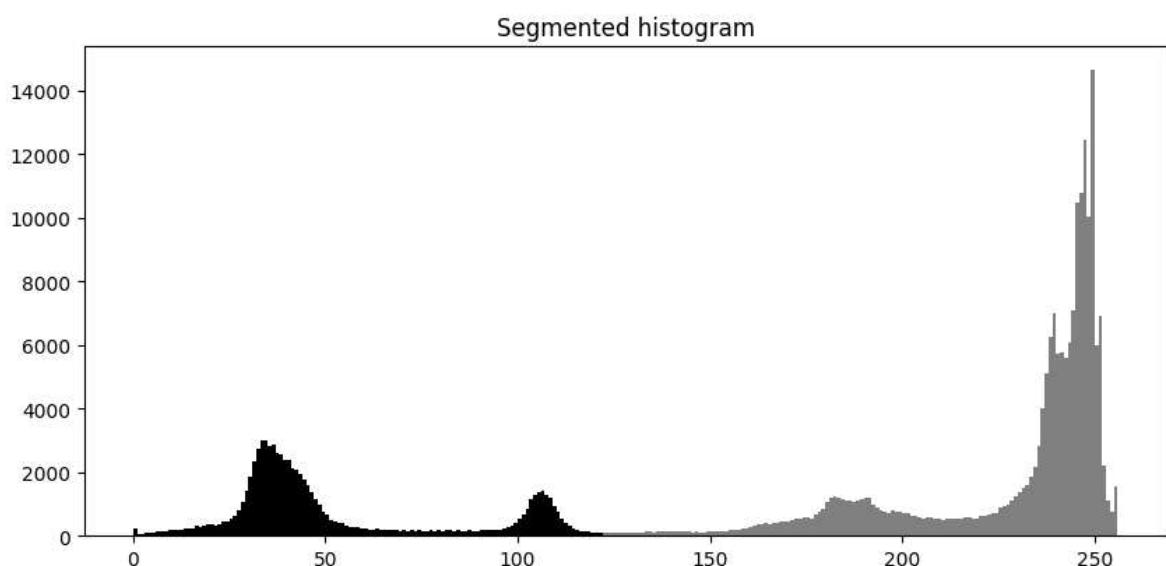

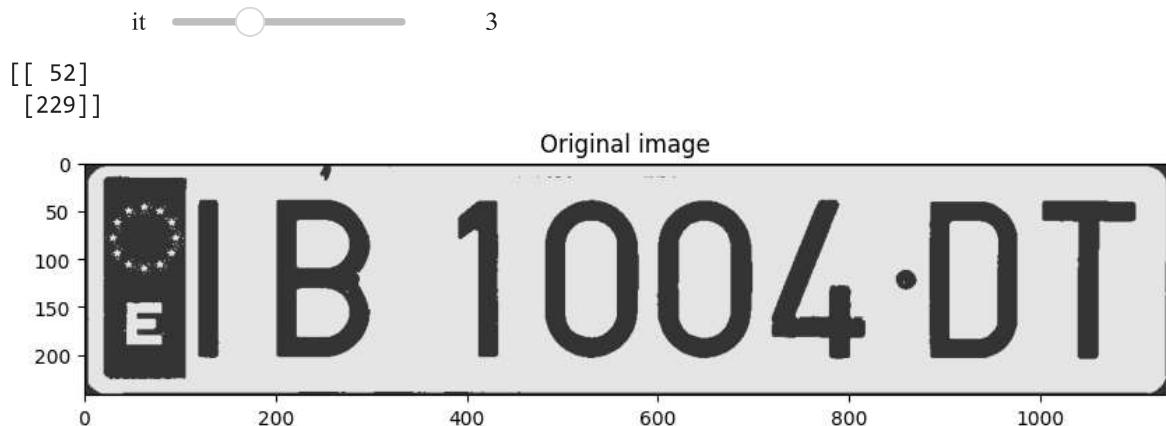

Attention to this!!! It is also remarkable the first function argument, which represents the data for clustering: an array of N-Dimensional points with float coordinates. Such array has the shape

num_samples × num_features, i.e., it has as many rows as samples (pixels in the image), and as many columns as features describing those samples (for example, if using the intensity of a pixel in a grayscale image, there is only one feature). For that, the code line `image.reshape((-1,1))` convert the initial grayscale image with dimensions 242×1133 into a flattened version of it with dimension 274186×1 , that is, 274186 samples (or pixels) with only one feature, its intensity. Take a look at `np.reshape()` to see how it works.

Below it is provided an interactive code so you can play with `cv2.kmeans()` by calling it with different `it` values.

As you can see, if k=2 in a grayscale image, it is a binarization method that doesn't need to fix a manual threshold. We could have used it, for example, when dealing with the plate recognition problem!

```
In [3]: matplotlib.rcParams['figure.figsize'] = (10.0, 10.0)
image = cv2.imread(images_path + 'plate.jpg',0)
interact(binarize_kmeans, image=fixed(image),it=(2,5,1));
```

Notice that for 1D spaces and not high-resolution images k-means is very fast! (it only needs a few iterations to converge). What happens if k-means is applied to color images (3D space) in

order to get color quantization?

Now that you know how k-means works, you can experimentally answer such question!

ASSIGNMENT 1: Playing with K-means

Write an script that:

- applies k-means to `malaga.png` with different values for K : $K = 4$, $K = 8$ and $K = 16$, setting `epsilon=0.2` and `it=10` as convergence criteria, and
- shows, in a 2×2 subplot, the 3 resulting images along with the input one.

Notice that in this case we are using 3 features per pixel, their R, G and B values, so the input data for the `kmeans` function has the dimensions `num_pixels × 3`.

Expected output:

```
In [4]: # Assignment 1
matplotlib.rcParams['figure.figsize'] = (15.0, 12.0)

# Read RGB image
image = cv2.imread(images_path + "malaga.png")
image = cv2.cvtColor(image, cv2.COLOR_BGR2RGB)

# Flatten image
flattened_img = image.reshape((-1, 3))
flattened_img = np.float32(flattened_img)

# Set criteria
it = 10
epsilon = 0.2
criteria = (cv2.TERM_CRITERIA_EPS + cv2.TERM_CRITERIA_MAX_ITER, it, epsilon)

# Apply k-means. Keep the third argument as None!
_, label4, center4=cv2.kmeans(flattened_img,4,None,criteria,30,cv2.KMEANS_RANDOM_CENTERS)
_, label8,center8=cv2.kmeans(flattened_img,8,None,criteria,30,cv2.KMEANS_RANDOM_CENTERS)
_, label16,center16=cv2.kmeans(flattened_img,16,None,criteria,30,cv2.KMEANS_RANDOM_CENTERS)

# Colour resultant labels
center4 = np.uint8(center4)
center8 = np.uint8(center8)
center16 = np.uint8(center16)

# Get the color (center) assigned to each pixel
res4 = center4[label4.flatten()]
res8 = center8[label8.flatten()]
res16 = center16[label16.flatten()]

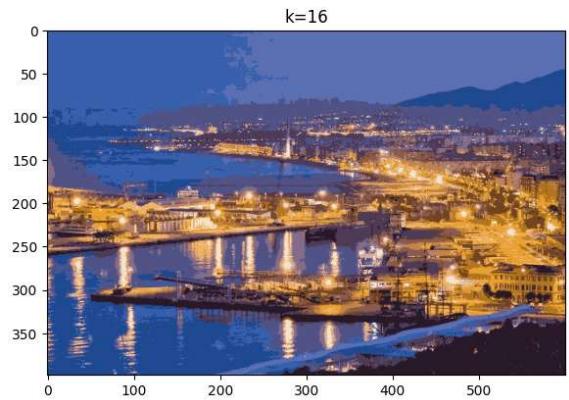

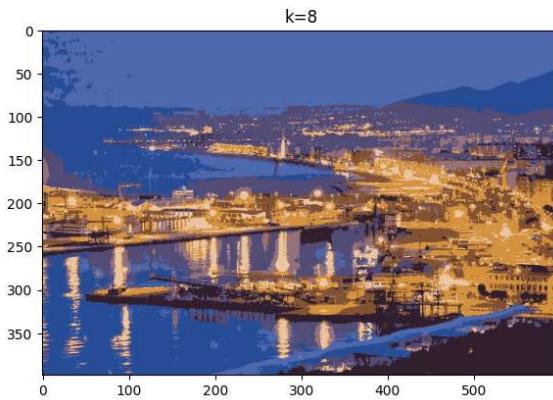

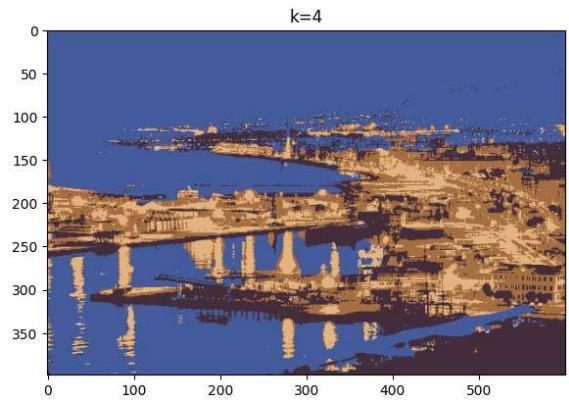

# Reshape to original shape
quantized4 = res4.reshape((image.shape))
quantized8 = res8.reshape((image.shape))
quantized16 = res16.reshape((image.shape))

# Show original image
plt.subplot(2,2,1)
plt.title("Original image")
plt.imshow(image)
```

```
# Show k=4
plt.subplot(2,2,2)
plt.title("k=4")
plt.imshow(quantized4)

# Show k=8
plt.subplot(2,2,3)
plt.title("k=8")
plt.imshow(quantized8)

# Show k=16
plt.subplot(2,2,4)
plt.title("k=16")
plt.imshow(quantized16);
```

Thinking about it (1)

Now, answer the following questions:

- What `cv2.kmeans()` is doing in each iteration?

En cada iteración calcula las medias m_k de los K clústers, y agrupa cada pixel con su centroide más cercano. El centroide se va desplazando con cada iteración, y el algoritmo para cuando se alcanza el número máximo de iteraciones o cuando la diferencia en el movimiento del centroide de una iteración a otra es menor que epsilon.

- What number of maximum iterations did you use? Why?

He usado 10 iteraciones ya que es lo recomendado como criterio de convergencia al principio del assignment. Además, para valores mayores a 10, no hay mucha diferencia entre las imágenes, así que es un buen punto dado que además no requiere de mucho tiempo de ejecución.

- How could we compress these images so they require less space in memory? Note: consider that a pixel in RGB needs 3 bytes to be represented, 8 bits per band.

Podríamos usar YCrCb, ya que es más eficiente a la hora de codificar la información y ocupará menos espacio que la imagen en RGB.

Analyzing execution times

In this exercise you are asked to compare the execution time of K-means in a grayscale image, with K-means in a RGB image. Use the image `malaga.png` for this task, and use the same number of clusters and criteria for both, the grayscale and the RGB images.

Tip: how to measure execution time in Python

In [5]:

```
import time

print("Measuring the execution time needed for ...")

K = 2

# Read images
image = cv2.imread(images_path + "malaga.png")
image = cv2.cvtColor(image, cv2.COLOR_BGR2RGB)
gray = cv2.cvtColor(image, cv2.COLOR_RGB2GRAY)

# Set criteria
it = 10
epsilon = 0.2
criteria = (cv2.TERM_CRITERIA_EPS + cv2.TERM_CRITERIA_MAX_ITER, it, epsilon)

start = time.process_time() # Start timer

# Flatten image
flattened_img = image.reshape((-1,3))
flattened_img = np.float32(flattened_img)

# Apply k-means
_,label,center=cv2.kmeans(flattened_img,K,None,criteria,30,cv2.KMEANS_RANDOM_CENTERS)

print("K-means in the RGB image:", round(time.process_time() - start,5), "seconds") #

start = time.process_time() # Start timer

# Flatten image
flattened_img = gray.reshape((-1,1))
flattened_img = np.float32(flattened_img)

# Apply k-means
_,label,center=cv2.kmeans(flattened_img,K,None,criteria,30,cv2.KMEANS_RANDOM_CENTERS)

print("K-means in the grayscale image:", round(time.process_time() - start,5), "second")
```

Measuring the execution time needed for ...
 K-means in the RGB image: 0.375 seconds
 K-means in the grayscale image: 0.34375 seconds

5.2.2 Expectation-Maximization (EM)

Expectation-Maximization (EM) is the generalization of the K-means algorithm, where each cluster is represented by a Gaussian distribution, parametrized by a mean and a covariance matrix, instead of just a centroid. It's a *soft clustering* since it doesn't give *hard* decisions where a pixel belongs or not to a cluster, but the probability of that pixel belonging to each cluster C_j , that is, $p(x|C_j) \sim N(\mu_j, \Sigma_j)$. This implies that at each algorithm iteration not just the mean of each cluster is refined (as in K-means), but also their covariance matrices.

Before going into detail on the theory behind EM, it is worth seeing how it performs in the car plate problem. OpenCV provides a class implementing the needed functionality for applying EM segmentation to an image, called `cv2.ml.EM()`. All methods and parameters are fully detailed in the documentation, so it is a good idea to take a look at it.

```
In [6]: matplotlib.rcParams['figure.figsize'] = (10.0, 10.0)
cv2.setRNGSeed(5)

# Define parameters
n_clusters = 2
covariance_type = 0 # 0: covariance matrix spherical. 1: covariance matrix diagonal. 2
n_iter = 10
epsilon = 0.2

# Create EM empty object
em = cv2.ml.EM_create()

# Set parameters
criteria = (cv2.TERM_CRITERIA_EPS + cv2.TERM_CRITERIA_MAX_ITER, n_iter, epsilon)
em.setClustersNumber(n_clusters)
em.setCovarianceMatrixType(covariance_type)
em.setTermCriteria(criteria)

# Read grayscale image
image = cv2.imread(images_path + "plate.jpg",0)

# Flatten image
flattened_img = image.reshape((-1,1))
flattened_img = np.float32(flattened_img)

# Apply EM
_, _, labels, _ = em.trainEM(flattened_img)

# Reshape Labels to image size (binarization)
binarized = labels.reshape((image.shape))

# Show original image
plt.subplot(2,1,1)
plt.title("Binarized image")
plt.imshow(binarized, cmap="gray")

# ----- Gaussian visualization -----

plt.subplot(2,1,2)
plt.title("Probabilities of the clusters")

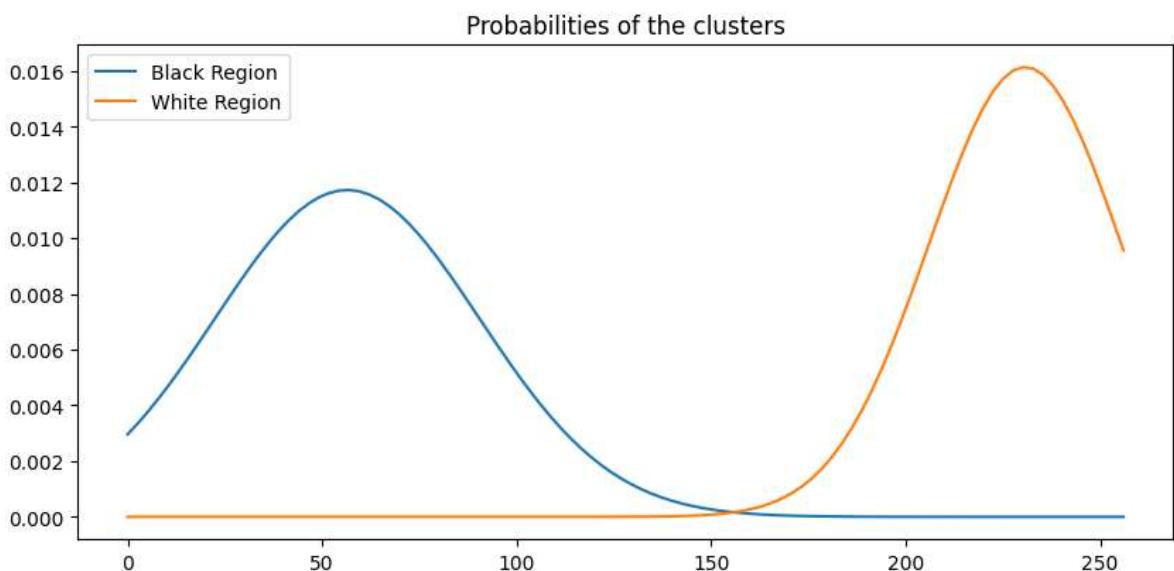

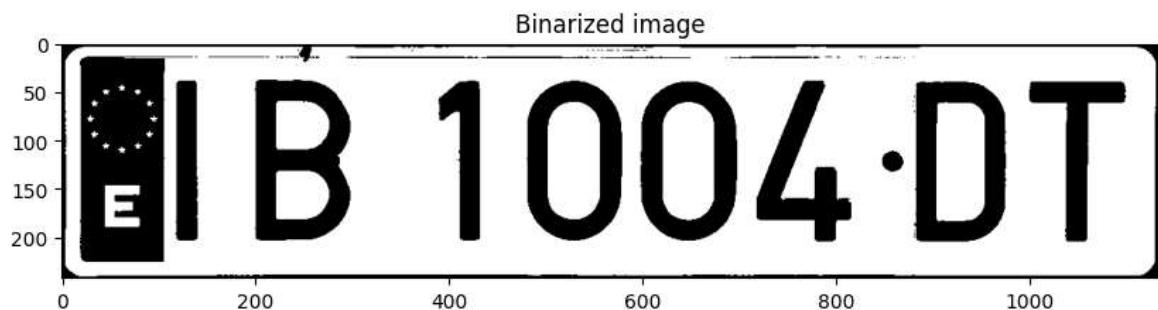

# Get means and cova (for grayscale 1D both)
means = em.getMeans()
cova = em.getCoVs()

# Get standard deviation as numpy array
sigmas = np.sqrt(cova)
sigmas = sigmas[:,0,0]
```

```
# Cast List to numpy array
means = np.array(means)[:,0]

# Plot Gaussians
x = np.linspace(0, 256, 100)
plt.plot(x, stats.norm.pdf(x, loc = means[0], scale = sigmas[0]))
plt.plot(x, stats.norm.pdf(x, loc = means[1], scale = sigmas[1]))
plt.legend(['Black Region', 'White Region'])

plt.show()
```

As you can see, although in OpenCV k-means is implemented as a method and EM as a class, they operate in a similar way. In the example above, we are segmenting a car plate into two clusters, and **each cluster is defined by a Gaussian distribution** (a Gaussian distribution for the black region, and another one for the white region). This is the basis of EM, **but how it works?**

EM is an iterative algorithm that is divided into two main steps:

- First of all, it **initializes the mean and covariance matrix of each of the K clusters**. Typically, it picks at random (μ_j, Σ_j) and $P(C_j)$ (prior probability) for each cluster j .
- Then, it keeps iterating doing Expectation-Maximization steps until some stopping criteria is satisfied (e.g. when no change occurs in a complete iteration):
 1. **Expectation step:** calculate the probabilities of every point belonging to each cluster, that is $p(C_j|x_i), \forall i \in data$:

$$P(C_j|x_i) = \frac{p(x_i|C_j)p(C_j)}{p(x_i)} = \frac{p(x_i|C_j)p(C_j)}{\sum_i P(x_i|C_j)p(C_j)}$$

assign x_i to the cluster C_j with the highest probability $P(C_j|x_i)$.

2. Maximization step: re-estimate the cluster parameters ((μ_j, Σ_j) and $p(C_j)$) for each cluster j knowing the expectation step results, which is also called *Maximum Likelihood Estimate* (MLE):

$$\mu_j = \frac{\sum_i p(C_j|x_i)x_i}{\sum_i p(C_j|x_i)}$$

$$\sum_j = \frac{\sum_i p(C_j|x_i)(x_i - \mu_j)(x_i - \mu_j)^T}{\sum_i p(C_j|x_i)}$$

\[5pt]

$$p(C_j) = \sum_i p(C_j|x_i)p(x_i) = \frac{\sum_i p(C_j|x_i)}{N}$$

Note that if no other information is available, the priors are considered equally probable.

Fig 4. Example of an execution of the EM algorithm with two clusters, with details about the evolution of their associated Gaussian distributions.

Doesn't it remind you to the K-means algorithm? **What is the difference between them?**

The main difference is that K-means employs the **euclidian distance** to measure how near is a point to a cluster. In EM we use a distance in which **each dimension is weighted** by the **covariance matrix** of each cluster, which is also called **Mahalanobis distance**. Furthermore, for k-means a point of data **belongs or not to** a cluster, in EM a point of data have a higher or lower **probability** to belong to a cluster. The table below summarizes other differences:

	K-means	EM
Cluster representation	Mean	Mean, (co)variance
Cluster initialization	Randomly select K means	Initialize K Gaussian distributions (μ_j, Σ_j) and $P(C_j)$
Expectation: Estimate the cluster of each data	Assign each point to the closest mean	Compute $P(C_j x_i)$
Maximization: Re-estimate the cluster parameters	Compute means of current clusters	Compute new (μ_j, Σ_j) , $P(C_j)$ for each cluster j

If you still curious about EM, you can find [here](#) a more detailed explanation.

OpenCV pill

Going back to code, working with EM we have to specify a covariance matrix type using `em.setCovarianceMatrixType()`. Also, when you applying `em.trainEM()` it doesn't return the centroid of the clusters, it is possible to get them calling `em.getMeans()`.

ASSIGNMENT 2: Color quantization with YCrCb color space

In the next example, color quantization is realized using the YCrCb color space instead of RGB. Recall that you have more info about such a space available in [Appendix 12.2 Color spaces](#). In this way, color quantization is only applied to the two color bands Cr and Cb, neglecting the grayscale one Y.

Notice that in this case, the feature space has 2 dimensions, one for the Cr band, and another dimension for the Cb, hence the feature vector describing the i^{th} pixel results $x_i = [Cr_i, Cb_i]$.

Let's see how it works!

What to do? Test and understand the following code.

```
In [7]: # Assignment 2
matplotlib.rcParams['figure.figsize'] = (15.0, 15.0)
cv2.setRNGSeed(5)

# Define parameters

n_clusters = 3 # Don't modify this parameter for this exercise

covariance_type = 1 # 0: Spherical covariance matrix. 1: Diagonal covariance matrix. 2
n_iter = 10
epsilon = 0.2

# Create EM empty object
em = cv2.ml.EM_create()

# Set parameters
criteria = (cv2.TERM_CRITERIA_EPS + cv2.TERM_CRITERIA_MAX_ITER, n_iter, epsilon)
em.setClustersNumber(n_clusters)
em.setCovarianceMatrixType(covariance_type)
em.setTermCriteria(criteria)

# Read color image
image = cv2.imread(images_path + "malaga.png")

# Convert to YCrCb
image = cv2.cvtColor(image, cv2.COLOR_BGR2YCrCb)

# Take color bands (2 lasts)
color_bands = image[:, :, 1:3]

# Flatten image
flattened_img = color_bands.reshape((-1, 2))
flattened_img = np.float32(flattened_img)

# Apply EM
_, _, labels, _ = em.trainEM(flattened_img)

# Colour resultant labels
centers = em.getMeans()
centers = np.uint8(centers)
res = centers[labels.flatten()]
```

```

# Reshape to original shape
color_bands = res.reshape((image.shape[0:2]) + (2,))

# Merge original first band with quantized color bands
quantized = np.zeros(image.shape)
quantized[:, :, 0] = image[:, :, 0]
quantized[:, :, [1, 2]] = color_bands

# Cast to unsigned data type
quantized = np.uint8(quantized)

# Reconvert to RGB
quantized_rgb = cv2.cvtColor(quantized, cv2.COLOR_YCrCb2RGB)
image_rgb = cv2.cvtColor(image, cv2.COLOR_YCrCb2RGB)

# Show original image
plt.subplot(1,2,1)
plt.title("Original image")
plt.imshow(image)

# Show resultant image
plt.subplot(1,2,2)
plt.title("YCrCb quantized colors (3 colors)")
plt.imshow(quantized);

```

Thinking about it (2)

Once you understood the code above, **answer the following questions:**

- What are the dimensions of the means u_j and the covariance matrices Σ_j ?

u_j tiene dimensión 3×2 , ya que usamos 3 clústers y tenemos 2 bandas de colores, mientras que las matrices de covarianza Σ_j tienen dimensión 2×2 .

- What are the dimensions of the input to `trainEM()`? Why?

Dado que la dimensión de la imagen en escala de grises es 242×1133 y la hemos convertido a una versión aplanada de dimensión 274186×2 , dado que hemos usado `.reshape(-1,2)` debido a que una imagen en YCrCb usa 2 bandas de colores.

- Why are the obtained results so good using only 3 clusters?

Porque con 3 clústers podemos representar RGB fácilmente, asociando un color a cada clúster (rojo, verde y azul).

- What compression would be better in terms of space in memory, a 16-color compression in a RGB image (that is, each band uses 16 different colors instead of the original 256) or a 4-

color compression in a YCrCb image? Hint: consider the bits needed to codify such information. Hint 2: the grayscale band in YCrCb, that is, Y, is not compressed.

Ambas serían iguales, ya que tendríamos $16 \times 16 \times 16$ combinaciones que resultan en $4+4+4 = 12$ bits necesarios para codificar la información, mientras que de la otra forma tenemos $256 \times 4 \times 4$, que acaban siendo $8+2+2 = 12$ bits también. (Los 256 en el segundo caso surgen de los 256 posibles valores de intensidad en la imagen gris).

Diving deeper into covariance matrices

There are 3 types of covariance matrices: **spherical covariances**, **diagonal covariances** or **full covariances**:

Fig 5. Examples of different types of covariance matrices.

ASSIGNMENT 3: Visualizing clusters from EM

Next, you have a code for visualizing the clusters in the YCrCb color space using EM.

What to do? Run the previous example modifying the type of covariance in the EM algorithm and visualize the changes using the following code.

```
In [8]: # Assignment 3
matplotlib.rcParams['figure.figsize'] = (10.0, 10.0)

# Get means (2D) and covariance matrices (2x2)
means = np.array(em.getMeans())
covs = np.array(em.getCovs())

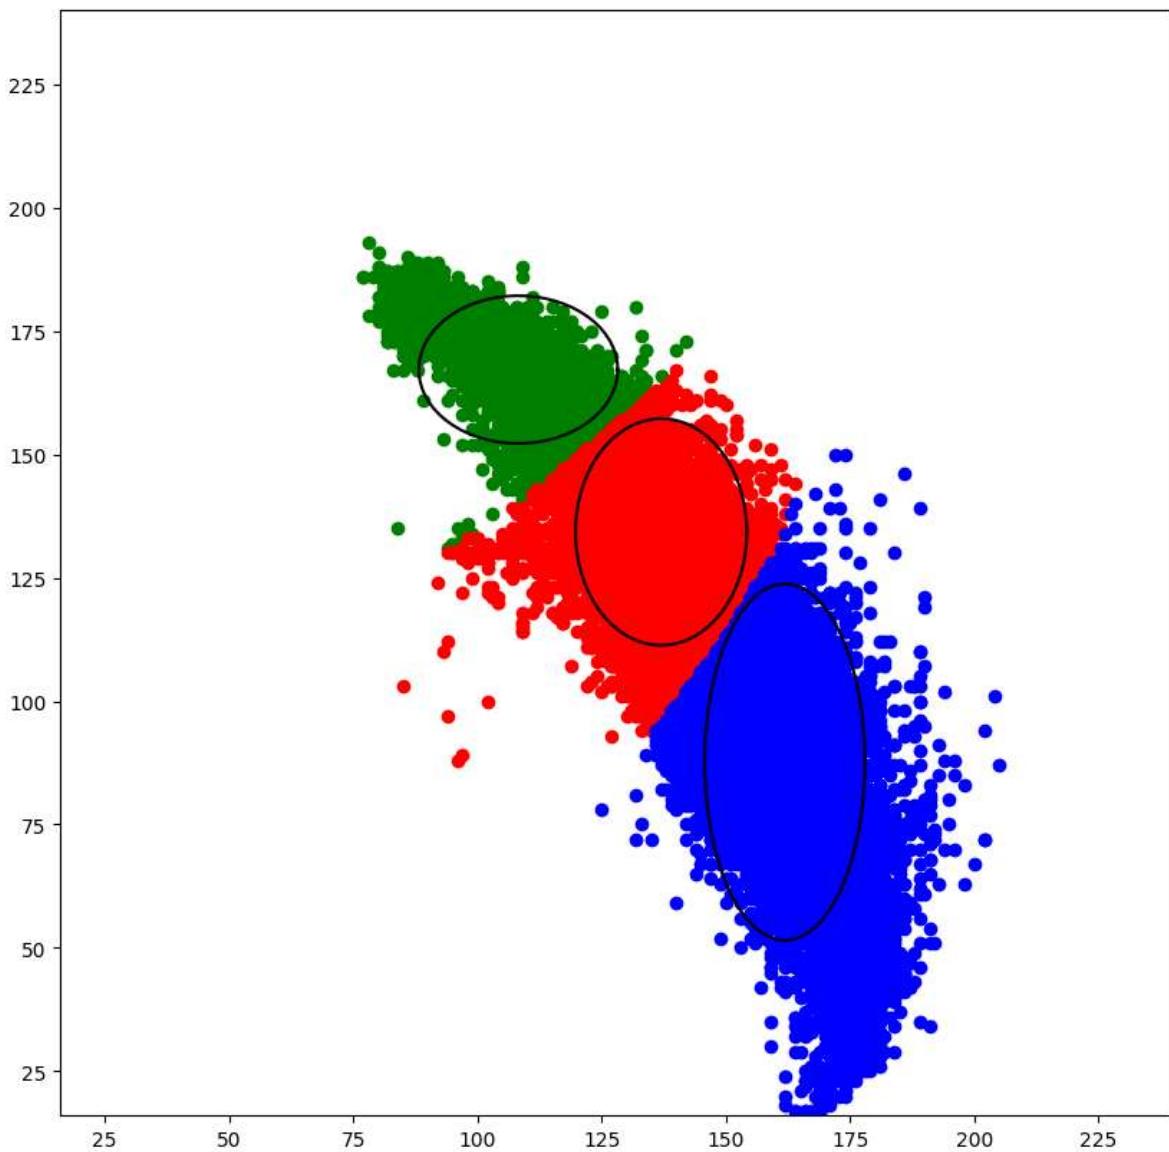

# Create figure
fig, ax = plt.subplots()
plt.axis([16, 240, 16, 240])

# Get points contained in each cluster
cluster_1 = np.any(color_bands == np.unique(res, axis=0)[0,:], axis=2)
cluster_2 = np.any(color_bands == np.unique(res, axis=0)[1,:], axis=2)
cluster_3 = np.any(color_bands == np.unique(res, axis=0)[2,:], axis=2)
cluster_1 = image[cluster_1]
cluster_2 = image[cluster_2]
cluster_3 = image[cluster_3]

# Plot them
plt.plot(cluster_1[:,1], cluster_1[:,2], 'go')
plt.plot(cluster_2[:,1], cluster_2[:,2], 'ro')
plt.plot(cluster_3[:,1], cluster_3[:,2], 'bo')

# Plot ellipses representing covariance matrices
PlotEllipse(fig, ax, np.vstack(means[0,:]), covs[0,:,:], 2, color='black')
PlotEllipse(fig, ax, np.vstack(means[1,:]), covs[1,:,:], 2, color='black')
PlotEllipse(fig, ax, np.vstack(means[2,:]), covs[2,:,:], 2, color='black')

fig.canvas.draw()
```

Thinking about it (3)

Answer the following questions about how clustering works in EM:

- What are the differences between each type of covariance?

La forma en la que se agrupan los píxeles de cada clúster. Con una covarianza esférica los píxeles se amontonan alrededor de un círculo. Con una covarianza diagonal los píxeles se agrupan alrededor de una elipse. Con una covarianza completa los píxeles se amontonan alrededor de una elipse orientada diagonalmente. Dentro de estos tres tipos, los resultados son similares en cuanto a agrupación de píxeles con el tipo 0 (esférica) y 1 (diagonal), sin embargo vemos una clara diferencia en la agrupación respecto a las anteriores al usar el tipo 2 (completa). (Cuando mencionamos círculos o elipses nos referimos a uno por clúster).

- What type of covariance makes EM equivalent to k-means?

Your answer here!

ASSIGNMENT 4: Applying EM considering different color spaces

It's time to show what you have learned about **EM** and **color spaces**!

What is your task? You are asked to **compare color quantization in a RGB color space and in a YCrCb color space.**

For that:

- apply Expectation-Maximization to `malaga.png` using 4 clusters (colors) to both the RGB-space image and the YCrCb-space one,
- and display both results along with the original image.

Expected output:

```
In [9]: # Assignment 4
matplotlib.rcParams['figure.figsize'] = (15.0, 12.0)
cv2.setRNGSeed(5)

# Define parameters
n_clusters = 4
covariance_type = 2 # 0: covariance matrix spherical. 1: covariance matrix diagonal. 2
n_iter = None
epsilon = None

# Create EM empty objects
em = cv2.ml.EM_create()

# Set parameters
criteria = (cv2.TERM_CRITERIA_EPS + cv2.TERM_CRITERIA_MAX_ITER, n_iter, epsilon)

em.setClustersNumber(n_clusters)
em.setCovarianceMatrixType(covariance_type)
em.setTermCriteria(criteria)

# Read image
image = cv2.imread(images_path + "malaga.png")

# Convert image to RGB
image_RGB = cv2.cvtColor(image, cv2.COLOR_BGR2RGB)

# Convert image to YCrCb
image_YCrCb = cv2.cvtColor(image, cv2.COLOR_BGR2YCrCb)

# Flatten RGB image
flattened_RGB = image_RGB.reshape((-1,3))
flattened_RGB = np.float32(flattened_RGB)

# Flatten color bands of YCrCb image
color_bands_YCrCb = image_YCrCb[:, :, 1:3]
flattened_YCrCb = color_bands_YCrCb.reshape((-1,2))
flattened_YCrCb = np.float32(flattened_YCrCb)

# Apply EM and get centers of clusters
_, _, labels_RGB, _ = em.trainEM(flattened_RGB)
centers_RGB = em.getMeans()
centers_RGB = np.uint8(centers_RGB)

_, _, labels_YCrCb, _ = em.trainEM(flattened_YCrCb)
centers_YCrCb = em.getMeans()
centers_YCrCb = np.uint8(centers_YCrCb)

# Colour resultant labels
```

```

res_RGB = centers_RGB[labels_RGB.flatten()]
res_YCrCb = centers_YCrCb[labels_YCrCb.flatten()]

# Reshape to original shape
quantized_RGB = res_RGB.reshape((image.shape))
quantized_colors_YCrCb = res_YCrCb.reshape((image.shape[0:2]) + (2,))

# Merge original first band with quantized color bands for YCrCb image
quantized_YCrCb = np.zeros(image.shape)
quantized_YCrCb[:, :, 0] = image_YCrCb[:, :, 0]
quantized_YCrCb[:, :, [1, 2]] = quantized_colors_YCrCb

# Cast YCrCb image to unsigned data type
quantized_YCrCb = np.uint8(quantized_YCrCb)

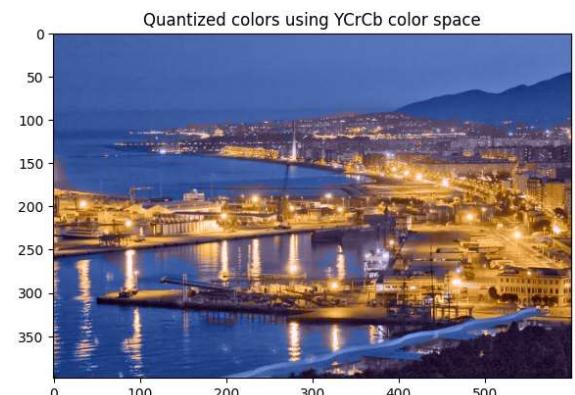

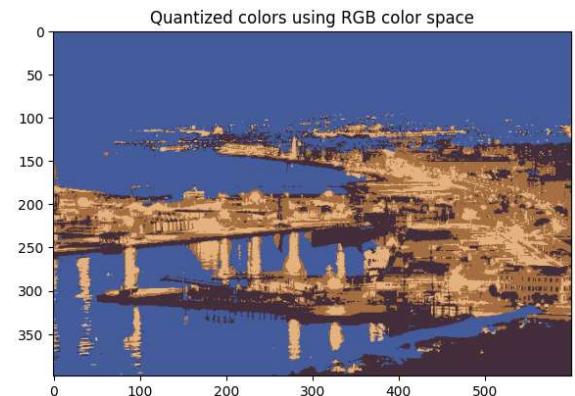

# Reconvert YCrCb image back to RGB
quantized_YCrCb = cv2.cvtColor(quantized_YCrCb, cv2.COLOR_YCrCb2RGB)

# Show original image
plt.subplot(2,2,1)
plt.title("Original image")
plt.imshow(image_RGB)

# Show resultant quantization using RGB color space
plt.subplot(2,2,2)
plt.title("Quantized colors using RGB color space")
plt.imshow(quantized_RGB)

# Show resultant quantization using YCrCb color space
plt.subplot(2,2,4)
plt.title("Quantized colors using YCrCb color space")
plt.imshow(quantized_YCrCb);

```

Conclusion

Congratulations for getting this work done! You have learned:

- how k-means clustering works and how to use it,
- how EM algorithm performs and how to employ it,
- how to carry out color quantization and the importance of color spaces in this context, and
- some basics for image compression.

ASSIGNMENT 4: Applying EM considering different color spaces

It's time to show what you have learned about **EM** and **color spaces!**

What is your task? You are asked to **compare color quantization in a RGB color space and in a YCrCb color space.**

For that:

- apply Expectation-Maximization to `malaga.png` using 4 clusters (colors) to both the RGB-space image and the YCrCb-space one,
- and display both results along with the original image.
